

Assignment 2

Hongyu He (2632195) & Bruno Hoevelaken (2645065)

Group CS 6

& Theoretical exercises

Exercise 2.1 (Additional exercises 1.3)

“+/-”: positive/negative results; “disease/ !disease”: have/don’t have cancer

a)

$$\begin{aligned} P(+) &= P(+ \mid \text{disease}) * P(\text{disease}) + P(+ \mid \text{!disease}) * P(\text{!disease}) \\ &= 0.95 * 0.004 + (1-0.95) * (1-0.004) \\ &= 0.054 \end{aligned}$$

The probability $P(+)$ calculated here is called **belief** in statistics, representing the possibility of a certain event happening, whilst the probability $P(\text{disease} \mid +)$ calculated in the additional exercises is called **conditional probability** illustrating the possibility of a certain event happening based on a **revised model** tuned by new information (an event has already happened).

b)

$$\begin{aligned} P(\text{disease} \mid +) &= P(\text{disease}) * P(+ \mid \text{disease}) / P(+) \\ &= 0.95 * 0.004 / 0.054 = 38 / 536 \\ &= 0.071 \end{aligned}$$

c)

(1) Yes, they are dependant because

$$\begin{aligned} P(\text{disease AND } +) &= P(\text{disease}) * P(+ \mid \text{disease}) \\ &= 0.004 * 0.95 \end{aligned}$$

is no the same as

$$P(\text{disease}) * P(+) = 0.004 * 0.054$$

(2) Yes, a test result was positive increase the risk of having cancer because

$$P(\text{disease} \mid +) == 0.071 > P(\text{disease}) == 0.004$$

Exercise 2.2

a)

Let \mathbf{X} denote the random variable ‘outcome of two 8-sided die-rolls’; Let \mathbf{x}_i (where $i = 1, 2, \dots, 64$) denote the possible outcomes

Because multiple rolls do not influence each other, we have

1)

$\mathbf{x}_1 == (1, 1); \mathbf{x}_2 == (1, 2); \mathbf{x}_3 == (1, 3); \mathbf{x}_4 == (1, 4); \mathbf{x}_5 == (1, 5); \mathbf{x}_6 == (1, 6); \mathbf{x}_7 == (1, 7); \mathbf{x}_8 == (1, 8);$

$\mathbf{x}_9 == (2, 1); \mathbf{x}_{10} == (2, 2); \mathbf{x}_{11} == (2, 3); \mathbf{x}_{12} == (2, 4); \mathbf{x}_{13} == (2, 5); \mathbf{x}_{14} == (2, 6); \mathbf{x}_{15} == (2, 7); \mathbf{x}_{16} == (2, 8);$

...

$\mathbf{x}_{57} == (8, 1); \mathbf{x}_{58} == (8, 2); \mathbf{x}_{59} == (8, 3); \mathbf{x}_{60} == (8, 4); \mathbf{x}_{61} == (8, 5); \mathbf{x}_{62} == (8, 6); \mathbf{x}_{63} == (8, 7); \mathbf{x}_{64} == (8, 8);$

2) $P(\mathbf{X}=\mathbf{x}_1) == P(\mathbf{X}=\mathbf{x}_2) == \dots == P(\mathbf{X}=\mathbf{x}_{64}) == 1/64$

b)

Let \mathbf{Y} denote the random variable ‘number of 1’s in two 8-sided die rolls’; Let \mathbf{y}_j (where $j = 1, 2, 3$) denote the possible outcomes

j	\mathbf{y}_j	$P(\mathbf{Y}=\mathbf{y}_j)$
1	0	49/64
2	1	7/32
3	2	1/64

c)

$$E(\mathbf{Y}) = 0 * 49/64 + 1 * 7/32 + 2 * 1/64 = 0.25 = 1/4$$

d)

$$\text{Var}(\mathbf{Y}) = 0^2 * 49/64 + 1^2 * 7/32 + 2^2 * 1/64 - E(\mathbf{Y})^2 = 7/32$$

e)

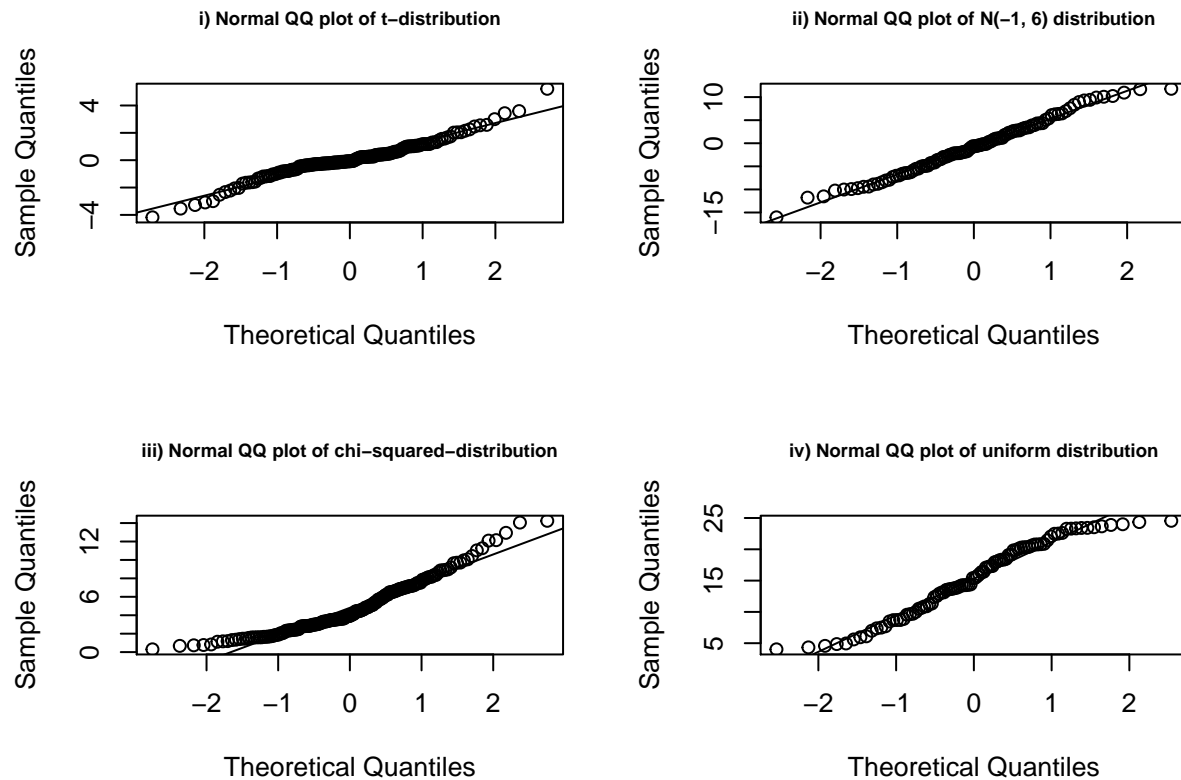

Since the sample size is much greater than 30, according to the **central limit theorem**, the random variables \mathbf{X}_i approximately have a normal distribution with an expectation μ of 1/4 and a standard deviation σ of $\sqrt{7/32}$, which is

$$N(1/4, \frac{7/32}{n})$$

& R-exercises

Exercise 2.3

a)

- i) The left part of the plot is below the QQ-line and the right part is above the QQ-line. Therefore, we conclude that both the left tail and right tail of the t-distribution is heavier than that of the standard normal distribution;
- ii) As the top-right figure demonstrates, because $N(-1, 6)$ and the standard normal are in the same **location-scale family**, the QQ-line of the $N(-1, 6)$ distribution adhere to the QQ-line of the standard distribution very well;
- iii) Both the left part and the right part of the plot are above the QQ-line. Therefore, we conclude that the left tail of the chi-squared-distribution is lighter than that of the standard normal distribution, whilst the right tail of the chi-squared-distribution is heavier than that of the standard normal distribution;
- iv) The left part of the plot is above the QQ-line and the right part is below the QQ-line. Therefore, we conclude that the left tail of the uniform distribution is heavier than that of the standard normal distribution, whilst the right tail of the uniform distribution is lighter than that of the standard normal distribution.

b)

(i) *titanic3.csv* dataset:

(1) According to the plots above, we conclude that the answer for the first question is **Normality cannot be excluded** for the following reasons:

- the histogram demonstrates a **roughly bell shape**;
- as the normal Q-Q plot shows, although the right tail is heavier and right tail is lighter, the major quantiles adhere to the Q-Q line and $y = \mu x + \sigma^2$ family;
- as we can see from the boxplot, excluding outliers, the density of the data, ranging from 1st quartile to 3rd quartile, lies in the middle of the range, as well as the median value. Thus, the distribution is **approximately symmetric**.

(2) **Peculiarities:**

- as the histogram shows, the left part of the distribution is not only heavier but also has an abnormal decreasing trend;
- the location of this distribution is dragged left (**left-skewed**) because of too many children.

(ii) *diabetes.csv* dataset:

- (1) According to the plots above, we conclude that the answer for the first question is **Normality cannot be excluded** for the following reasons:
- the histogram demonstrates a **roughly bell shape**;
 - as the normal Q-Q plot shows, although the right tail is lighter and right tail is heavier, the major quantiles adhere to the Q-Q line and $y = \mu x + \sigma^2$ family;
 - as we can see from the boxplot, excluding outliers, the density of the data, ranging from 1st quartile to 3rd quartile, lies in the middle of the range, as well as the median value. Thus, the distribution is **approximately symmetric**.
- (2) **Peculiarities:** As we can see from the histogram, there are some “holes” which represent absences of some certain cholesterol values.

(iii) *vlbw.csv* dataset:

- (1) according to the plots above, we conclude that the answer for the first question is **Obviously not from a normal distribution** for the following reasons:
- the shape of the histogram is by no means a **bell shape**;
 - as the normal Q-Q plot shows, although the major quantiles adhere to the Q-Q line and $y = \mu x + \sigma^2$ family, the left tail and, especially, the right tail horribly deviate from two lines;
 - as we can see from the boxplot, the distribution is quite **left-skewed** and therefore it is not **symmetric** whatsoever.
- (2) **Peculiarities:** Compared to the previous two datasets, this distribution demonstrates a more **centralized pattern** and there are **no outliers**.

Exercise 2.4

a)

As the diagram illustrates, when the number of trails becomes larger, the absolute difference of two die rolls converge to the theoretically expected value of the absolute difference 1.9444.

b)

(1)

```

source("function02.txt")
num_trails = 1000
outcomes = diffdice(num_trails)

E = 0
for (x_i in 1:6) {
  # calculate the probability of  $P(X=x_i)$ ;
  P_xi = length(outcomes[outcomes==x_i]) / num_trails
  # calculate the approximate expectation which is the weighted average of  $x_i$ ;
  E = E + x_i * P_xi
}

```

#	outcome	frequency
1	0	168
2	1	260
3	2	219
4	3	190
5	4	112
6	5	51

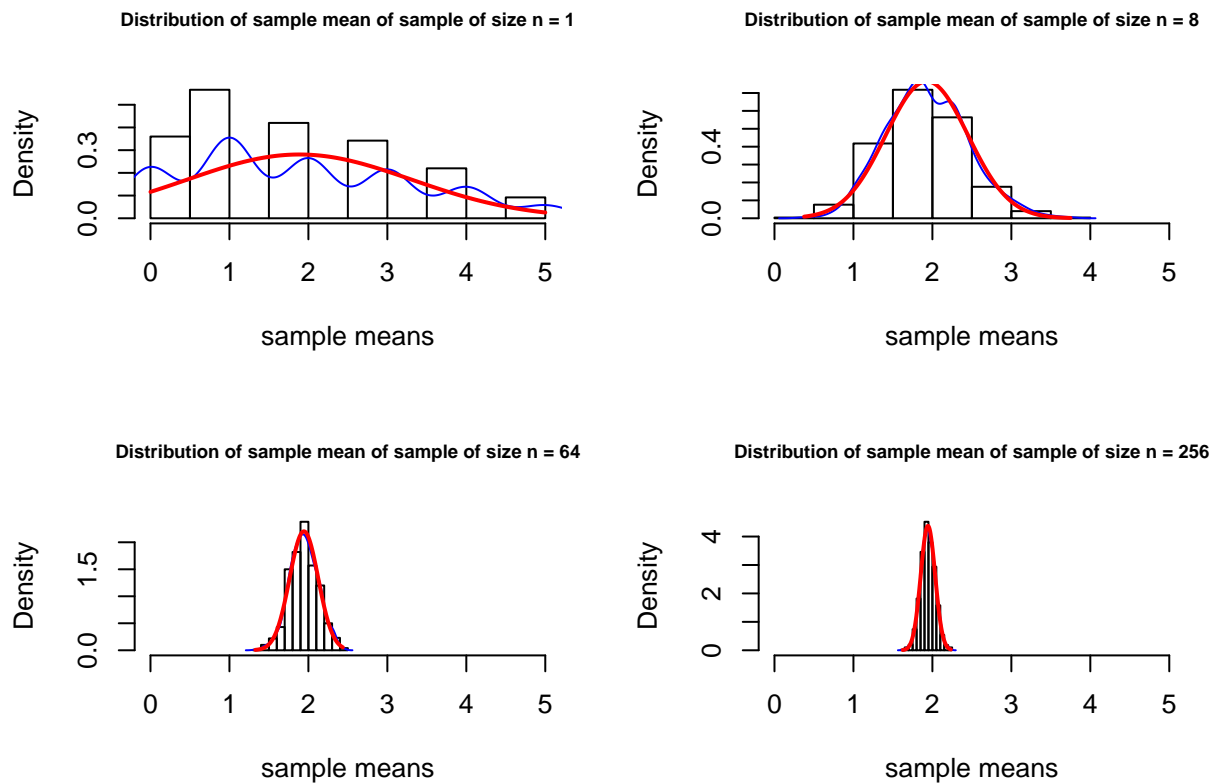

Using the function `diffdice`, we found an approximate value of expectation of the random variable ‘the absolute difference of two die rolls’: **1.971**

(2)

```
P_3 = length(outcomes[outcomes==3]) / num_trails
```

The probability of the event ‘the absolute difference of two die rolls is 3’ is 0.19

c)

d)

The blue lines in the above figures represent empirical distributions and the red lines are the normal distribution. As these plots demonstrate, those two lines gradually merge together as the sample size become larger. In other words, the distribution of the sample means steadily move toward a normal distribution.
